Neoproterozoic glacial deposits are systematically followed by enigmatic carbonates deposits well identified on several continents including Africa (Font, 2005). These carbonates deposits commonly called Cap carbonates are regarded as important keys for understanding the Neoproterozoic glacial events.

At least three glacial episodes are known during the Neoproterozoic (Hoffmann et al., 2004; Font, 2005): the Sturtian (750-700 Ma), the Marinoan (635 Ma) and the Gaskiers (580 Ma) glaciations. The Sturtian and the Marinoan are Early and Late Cryogenian glacial deposits, respectively, whereas the Gaskiers correspond to the Ediacaran glacial deposits.

The West African basins (Taoudenni, Voltaa and Gourma) contain Late Cryogenian glacial deposits overlied by carbonates that have been assimilated to postglacial carbonates (Trompette, 1973; Affaton 1990; Miningou et al., 2017).

The Firgoun area deposits, located on the eastern edge of the West African Craton area (Fig. 1), are assumed to be the equivalent to the basal deposits of the Ydouban Group (Gourma Basin).

In Firgoun area, the uppermost deposits include matrix-supported diamictites, cherts and carbonates. The occurrence of diamictite deposits, interbedded into the marine quartzitic sandstones beds and the presence of more or less recrystallized limestones and silexites could be considered as parts of the well-known Neoproterozoic Triad.

Two kinds of carbonate rocks lithofacies have been observed: unmetamorphosed brown dolomitic limestones and white marbles. The dolomitic limestones exhibit a cavernous appearance probably due to a post-depositional dissolution phenomenon (Fig. 2a). Marbles are massive deformed rocks (metacarbonates), with a milky white to pinkish appearance (Fig. 2b).
